Identification of solar periodicities in southern African baobab $\delta^{13}C$ record

Spectral analysis using wavelet, Lomb–Scargle and maximum entropy techniques of the proxy rainfall record of northeastern South Africa based on annual carbon isotope ($\delta^{13}C$) data obtained from baobab trees for the period 1600 AD – 2000 AD show clear evidence of the presence of characteristic solar periodicities. Solar periodicities that were identified above the 95% confidence level include the ~11-year Schwabe cycle, the ~22-year Hale cycle as well as the 80–110-year Gleissberg cycle. A Morlet wavelet analysis of the $\delta^{13}C$ data between 1600 AD and 1700 AD shows the effect of the Maunder sunspot minimum on both the Schwabe and Hale cycles during this time.

Significance:
A spectral analysis of $\delta^{13}C$ baobab tree ring data for southern Africa between 1600 AD and 2000 AD is presented. The results show – for the first time – that the $\delta^{13}C$ time series contains the 11-year Schwabe, 22-year Hale as well as the 80–110-year Gleissberg solar periodicities. In addition, the influence of the Maunder sunspot minimum between ~1650 AD and 1715 AD could also be clearly identified in the $\delta^{13}C$ data for the first time. These findings are of significant importance to investigations of solar influences on climate variability.

Introduction
Carbon isotope ratios have been used in the literature by several palaeoclimate researchers as a proxy for rainfall in a specific region where data were made available by tree ring investigations. During the process of photosynthetic uptake of carbon17, CO$_2$ by trees and plants, active discrimination occurs against $^{13}$CO$_2$, in favour of $^{12}$CO$_2$. During periods of high rainfall, rapid exchange of CO$_2$ with the atmosphere and trees takes place. During periods of low rainfall, on the other hand, the amount of CO$_2$ available for photosynthesis is restricted to only that inside leaves. Therefore, in regions of low rainfall, like southern Africa, lower $\delta^{13}C$ values are associated with wetter conditions, and higher $\delta^{13}C$ values are associated with drier conditions during the growth of the wood. In order to link carbon isotope ratios to rainfall, one is restricted to trees that only rely on precipitation as a water source. Carbon ratios from the African baobab (Adansonia digitata L.) have shown strong correlation with summer rainfall patterns in southern Africa in a previous study.

The sun is a variable star that exhibits changes on multiple spatial and temporal scales, and is the most important source of energy for the earth’s climate system (see for example a review on this topic by Gray et al. and the references therein). Solar activity is characterised by periodicities and cycles that vary on a variety of timescales. The most important periodicities are the ~11-year sunspot cycle (also known as the Schwabe cycle), the ~22-year magnetic cycle (also known as the Hale cycle), the 80–110-year Gleissberg cycle as well as the ~205–year De Vries cycle. These periodicities of solar origin have been identified in several tree ring records and cosmogenic data such as $^{10}$Be and $^{14}$C (see for example the review by Ussoskin and the references therein). Convincing evidence for solar influences on weather and climate has been found in the last ~150 years (Hoyt and Schatten and references therein). Souza Echer et al. found a clear correlation in the 22-year periodicity between global air surface temperature and sunspot number in the interval 1880–2000. Although solar signals have been detected in climate records (e.g. Beer et al.), one should keep in mind that climate and rainfall is a non-linear system and that several forces are involved in the process. Apart from the direct and indirect effects of solar irradiance (total solar irradiance and ultraviolet), particle radiation effects (solar energetic particles and cosmic rays) also have an effect on the troposphere (see Figure 21 in Gray et al.). Rigorzo et al. investigated the solar activity signals in tree ring data in Chile over a period of ~400 years, employing spectral analysis techniques. They found clear evidence for the presence of solar activity: Schwabe (~11-year), Hale (~22-year), fourth-harmonic of the 208-year De Vries cycle (~52-year) and Gleissberg (~80-year) cycles. Several investigations have indicated that solar variations had an effect on pre-industrial climate throughout the Holocene (the warm interval since the last ice age). These studies have been done in several parts across the globe and utilised a large variety of palaeoclimate proxies. The reader is referred to the recent review by Lockwood. An interesting finding by McKinnell and Crawford is the long-term linear-induced 9.3-year and 18.6-year cycles in the temperature records in some regions over a 400-year period. A wavelet analysis of centennial (1895–1994) rainfall data in southern Brazil by Souza Echer et al. confirmed the existence of strong 8.9-, 11.7- and 24.9-year periodicities. $^{14}$C time series studies on tree growth rings from Bashkoria (Russia) by Kocharov et al. revealed periods close to 21, 9.4 and 13.5 years using advanced spectral analysis methods. Damon et al. who also studied a time series of $\delta^{13}C$ in tree rings, for the time interval between 1065 AD and 1250 AD, confirmed these results. They also detected a period of ~52 years and attributed it to the fourth harmonic of the Suess or De Vries cycle. The climate of southern Africa is to a large extent semi-arid. Except for the southern coastal area, the southern African region receives almost all its rainfall in summer. A characteristic feature of the southern African rainfall record is the pronounced ~80-year cycle that can be traced back 3500 years.

In this investigation, $\delta^{13}C$ measurements obtained from the Pafuri 1000-year-old baobab trees were analysed between the years 1600 AD and 2000 AD to identify the presence of possible solar periodicities. Spectral analysis methods such as wavelets, Lomb–Scargle and maximum entropy were used to obtain statistically significant results above the 95% confidence level. In addition, a Morlet wavelet analysis of $\delta^{13}C$ between 1600 AD and
1700 AD was performed to investigate the variation in the strengths of, particularly, the Schwabe and Hale cycles during the Maunder sunspot minimum period of 1645–1715 AD (Eddy).23

Data and method of analysis
Woodborne et al.17 did a carbon isotope analysis of four South African baobab trees located in the Pafuri area (22°22.925'S, 31°13.145'E; 22°26.647'S, 31°04.745'E; 23°15.765'S, 31°33.309'E; 22°24.352'S, 31°16.676'E) in order to obtain a proxy for rainfall in this region. A map of southern Africa showing the location of the trees is given in Figure 1.

Three spectral analysis approaches were employed in this investigation to perform a spectral analysis of δ13C time series, namely the wavelet, the Lomb–Scargle periodogram method, and the maximum entropy method, in order to identify characteristic periodicities above the 95% confidence level. Wavelet analysis is used extensively to decompose a time series into time–frequency space and to establish the modes of variability, particularly when the time series under investigation contains non-stationary power at different periods. As the wavelet transform is a localised transform in both space (time) and frequency, this particular property can be usefully applied to extract information from the signal, which is not possible with Fourier techniques (Daubechies).25 All graphs and plots in this paper were produced using the SigmaPlot (www.systat.com) plotting package, while the contour plots were generated using the Interactive Data Language wavelet applet (http://www.exelisvis.com/ProductsServices/IDL.aspx).

Results and discussion
Morlet wavelet power spectra of order 6 were obtained by analysing the δ13C time series at a cadence of 1 year between 1600 AD and 1700 AD. This was done particularly to investigate the behaviour of the Schwabe (~11-year sunspot) cycle as well as the Hale (~22-year magnetic) cycle with time during this interval. The results can be seen in Figure 3 below.

From Figure 3, the 11-year Schwabe sunspot cycle as well as the 22-year Hale solar magnetic cycle can be clearly identified. It is interesting to note that the 11-year sunspot cycle could only be observed between ~1630 AD and 1650 AD above the 95% confidence level, while between ~1650 AD and 1700 AD it disappeared completely. This particular interval coincides with the sunspot Maunder Minimum (1645–1715 AD) when no sunspots could be observed on the surface of the sun and was also known as the Little Ice Age. In the northern hemisphere, extreme cold spells were experienced during the Little Ice Age. It is quite extraordinary that a disappearance of the 11-year Schwabe cycle on the sun did indeed coincide with a similar pattern in the δ13C data obtained from the summer rainfall region of southern Africa. The purpose of this investigation is not to show that rainfall is influenced by the sun, but that during extreme sunspot minimum conditions like the Maunder Minimum, we observe that solar periodicities like the 11-year Schwabe period in rainfall proxy parameters such as δ13C can indeed disappear or become statistically insignificant. On the other hand, due to the sub-dominant role of the 11-year periodicity during the Maunder Minimum, we observe a dominant 22-year periodicity in this time, supporting observations by Mursula et al.26 Similar observations during the Maunder Minimum in solar proxies showing a dominant 22-year periodicity accompanied by
a less-dominant Schwabe cycle have been reported by Silverman\textsuperscript{27} in aurora data and by Miyahara et al.\textsuperscript{28} in \(^{14}C\) data.

We proceeded with the analysis of \(^{13}C\) by performing a Lomb–Scargle spectral analysis between 1600 AD and 2000 AD at each 100-year interval in order to identify other prominent periodicities in the data. Results obtained are displayed in Figure 4.

From Figure 4a (and Table 1) a Lomb–Scargle analysis revealed periodicities in the \(^{13}C\) data at \(-18\) and \(22\) years above the 95% confidence level, while the \(10.3\)-year period is marginally statistically significant, confirming our wavelet analysis regarding the 11-year periodicity. The \(18\)-year period fits in with the general conclusion by Tyson et al.\textsuperscript{16} that climate variability in the 16–20-year range is a characteristic feature of southern Africa. However, one cannot exclude the possibility that this \(18\)-year periodicity can be linked to the lunar-induced 18.6-year cycle as reported by McKinnell and Crawford\textsuperscript{12}. This \(18\)-year cycle has been identified as a characteristic oscillation in southern African rainfall and has been extensively documented in the meteorological records. It appears predominantly in the summer rainfall tree-ring data, but could not be identified during 1700–1799 AD. Figure 4b, representing periodicities observed between 1700 AD and 1799 AD, shows a resurgence of both the 11-year as well as the 22-year cycles, while we also notice with interest the appearance of an 85-year period which represents the solar Gleissberg cycle. Variability at about 80 years has been observed on a global scale. A review by Hoyt and Schatten\textsuperscript{7} summarises its presence in temperature and precipitation data.

Cross-spectral analysis was subsequently performed to determine whether a statistically significant correlation exists between sunspot periodicities and the Pafuri \(^{13}C\) data between 1600 AD and 2000 AD. Cross-spectral analysis is a method to determine the common variability between two time series as a function of periodicity (frequency) and to

A cross-spectral analysis was subsequently performed to determine whether a statistically significant correlation exists between sunspot periodicities and the Pafuri \(^{13}C\) data between 1600 AD and 2000 AD. Cross-spectral analysis is a method to determine the common variability between two time series as a function of periodicity (frequency) and to
determine the coherency between them. The Fortran computer program REDFIT-X was used to determine the coherence between sunspot numbers and \( \delta^{13}C \) observations. Results obtained are shown in Figure 6.

![Figure 6: A cross-spectral analysis between annual mean sunspot numbers (ssn) and \( \delta^{13}C \) data between 1600 AD and 2000 AD.](image)

The cross-spectral results clearly show exceptionally strong coherence for the 11-year Schwabe cycle (>0.9) as well as the 45-year Gleissberg cycle (>0.8), while coherence for the 22-year Hale cycle was at a moderate level of 0.56. These results are all well above the 95% confidence level as displayed in Figure 6.

Conclusions

In this study, \( \delta^{13}C \) measurements from the Pafuri baobab trees between the years 1600 AD and 2000 AD have been analysed in order to identify the presence of possible well-known solar periodicities. Spectral analysis methods such as wavelets, Lomb–Scargle and maximum entropy were employed to obtain statistically significant results above the 95% confidence level. Results obtained show clear evidence of the presence of the 11-year Schwabe sunspot cycle, the 22-year Hale magnetic cycle as well as the 80–100-year Gleissberg solar cycle. In addition, the ~18-year period which is characteristic of southern African rainfall, could also be identified in our spectral analysis, confirming previous investigations of the rainfall pattern across this region. Previous investigations linked this periodicity to lunar-induced effects\(^1\) on sea-surface temperatures. A Morlet wavelet analysis of \( \delta^{13}C \) data, particularly concentrating on the time interval between 1600 AD and 1700 AD, revealed, in particular, that the Schwabe cycle could only be observed between ~1630 AD and 1650 AD above the 95% confidence level, while between ~1650 AD and 1700 AD it disappeared completely. This particular period coincides with the sunspot Maunder Minimum period when hardly any sunspots could be identified on the surface of the sun. This period is also known as the Little Ice Age when exceptionally low temperatures were recorded in Europe. To the best of our knowledge, this is the first identification of the presence of the Maunder Minimum in \( \delta^{13}C \) tree-ring data in southern Africa. In order to verify our results, we further performed a cross-spectral analysis of sunspot data and \( \delta^{13}C \) measurements between 1600 AD and 2000 AD. Evidence obtained from this analysis showed exceptionally strong coherence, particularly for the Schwabe and Gleissberg cycles, while a moderate coherence exists for the 22-year Hale cycle. Waple et al.\(^{31}\) investigated solar irradiance forcing on climate over a 200-year period between 1650 AD and 1850 AD preceding the industrial era with its anthropogenic influence. This era is characterised by a wide range of solar irradiance values and includes the Maunder Minimum. The authors conclude that on multi-decadal to century timescales, solar forcing is dominated by the ~90-year Gleissberg cycle, while at decadal timescales the 11-year and 22-year solar cycles dominate.

Sundqvist et al.\(^{32}\) analysed a 350-year \( \delta^{18}O \) stalagmite record from the summer rainfall region in South Africa and reported a positive correlation with regional air surface temperatures at interannual timescales. They found that during parts of the Little Ice Age, the regional temperature could have been ~1.5 °C colder than today. Prominent 22- and 11-year cycles also indicated that both the solar magnetic as well as the El Nino–Southern Oscillation cycle could be important drivers of multi-decadal to interannual climate variability in southern Africa. A surface water temperature reconstruction from Antarctica\(^{33}\) shows similar features and a cooling of more than 2 °C between 1300 AD and 1800 AD. These records show clear evidence that the Little Ice Age, originally identified in the northern hemisphere, also had a counterpart in the southern hemisphere. Peristykh and Damon\(^{34}\) did an interesting spectral analysis study of \( \delta^{13}C \) tree-ring data divided into intervals before, during and after the Maunder Minimum. They found that the ~22-year Hale cycle is most prominent during the Maunder Minimum, while the 11-year cycle is totally suppressed. In addition, they also reported that before the Maunder Minimum the Hale cycle had a period of 22.9 years, whereas during the minimum the cycle had two periodicities at 24 and 15.8 years, and after the minimum the Hale cycle had a period of 26 years. Our investigation also confirmed the existence of a 15.5-year periodicity during 1600–1699 AD, but periodicities observed between ~25 and 30 years were found to be below the 95% confidence level. They were therefore regarded as not statistically significant.

The results obtained in this investigation, in particular \( \delta^{13}C \) measurements from the Pafuri baobab trees in southern Africa between the years 1600 AD and 2000 AD, provide strong evidence of the presence of solar cycles. These \( \delta^{13}C \) isotope measurements are regarded by palaeoclimatologists as a proxy for rainfall in a particular region. Results obtained in this investigation can be regarded as the first identification of prominent solar cycles in \( \delta^{13}C \) tree-ring data in southern Africa. Of particular interest is the behaviour of the Schwabe cycle during the Maunder Minimum period between ~1650 AD and 1700 AD.
