Emerging potato pathogens affecting food security in southern Africa: Recent research

Potato is a staple crop that contributes to food security and poverty alleviation in developing nations. Despite this, yields in developing nations are often unsustainably low, due to various biotic and abiotic factors that negatively affect production. Some of the most important biotic constraints are pathogens, many of which are disseminated by seed tubers. The lack of functional or formal seed certification systems in many southern African countries results in a continual increase in pathogen pressure. Short rotation cycles, poor plant nutrition and inefficient control measures exacerbate the crop production challenges faced by resource poor growers. In this review, we discuss five of the most important diseases on potatoes in southern Africa, namely late blight, bacterial wilt, soft rot / blackleg, powdery scab and zebra chip. Management options for small-scale growers are provided.

Significance:
- Potato production in southern Africa is threatened by tuber-borne pathogens.
- Establishment and implementation of seed certification systems in southern African countries will increase potato yields and subsequently contribute to food security.
- Late blight, bacterial wilt, soft rot / blackleg and powdery scab are important emerging diseases on potatoes in southern Africa.
- Improved understanding of the biology of pathogens and the epidemiology of diseases will contribute to the management thereof.

Introduction

Potato is regarded as one of the most important crops in addressing the challenge of food security, particularly among smallholder farmers. Potato production has drastically increased since the 1960s in the developing world, in comparison to that in the developed world. However, the sustainability of potato production globally, and particularly in developing countries, is threatened by adverse abiotic conditions, pests and pathogens. Pest and pathogen control is difficult for subsistence potato growers in southern Africa – a region fraught with challenges, not least of which is the need to increase agricultural productivity in the face of climate change and a rapidly growing population.

Many of the important diseases affecting potato can be defined as emerging infectious diseases. Emerging infectious diseases are caused by pathogens that have (i) increased in incidence, geographical or host range; (ii) have changed pathogenesis; (iii) have newly evolved or (iv) have been discovered or newly described. Similarly, Secor and Rivera-Varas classified important potato diseases as caused by emerging, changing or surviving pathogens. The primary reasons for the occurrence of emerging infectious diseases in potatoes and other crops are related to increased trade and travel, intensified and expanded land use, changes in agricultural practices, planting of new varieties, and extreme weather events linked to climate change.

Using the classification proposed by Secor and Rivera-Varas, important diseases on potatoes in the last decade (2010–2020) in southern Africa include late blight, bacterial wilt, soft rot and blackleg, and powdery scab. Zebra chip disease, although not recorded in southern Africa, has been included as a threat because of its severe impact on potato production. In this review, we investigate the drivers behind the increase in these diseases, mitigation measures and routes to prevent additional emerging infectious diseases from appearing in the southern African potato industry.

Late blight

Late blight, caused by the oomycete Phytophthora infestans (Mont.) de Bary, is considered the most devastating potato disease globally, and causes severe yield losses when uncontrolled. The disease begins as small, light to dark green, circular to irregular-shaped water-soaked lesions on leaves. In cool, moist conditions the lesions expand to form dark brown to black lesions (Figure 1a), often surrounded by chlorotic halos. As the disease progresses, symptoms extend to petioles and haulms, eventually killing the plant (Figure 1b).

In some countries in sub-Saharan Africa, including southern Africa, where the majority of potato crops are produced by small-scale or subsistence growers, losses due to late blight are estimated to be as high as 40–70% in susceptible varieties. In the South African commercial potato production industry, however, late blight is not considered the most important yield limiting disease. Climatic conditions during potato growing seasons in most of the 16 growing regions in South Africa are sub-optimal for the development of late blight. Given the climate change forecast for the next few decades, it is also unlikely that late blight will increase in severity – in fact, the contrary has been predicted. However, the SimCastMeta model simulation by Sparks et al. for five different potato growing regions globally, has indicated that blight units in some other southern African countries may increase slightly in the period 1975–2050. These possible increases in disease could, however, be mitigated by shifting planting dates to avoid conditions favourable for the development of late blight.
Bacterial wilt

Bacterial wilt (or brown rot) is another serious disease of potatoes that can result in substantial yield losses. It is caused by members of the *Ralstonia solanacearum* species complex (RSSC). The first symptoms of the disease are wilting of the young leaves of plants, which is most commonly observed at the hottest time of day. As the disease progresses, plants become stunted, display general wilting and chlorosis, and will eventually die. The most obvious symptoms are noted in tubers, as an initial brown discolouration of the vascular tissue, followed by rotting thereof (Figure 2a and 2b). Members of the RSSC globally were previously assigned to four phylotypes, with phylotype classification based on phylogenetic analysis of the 16S-23S ITS region. However, Safni et al.22 elevated these phylotypes to species level. The phylotypes generally correlate with the geographical origin of the strains: phylotype II originating from the Americas was assigned to *R. solanacearum*, strains in phylotype IV from Indonesia were assigned to *R. syzygii*, and strains in phylotype I and III originating from Asia and Africa were assigned to *R. pseudosolanacearum*. The most threatening potato pathogens, causing bacterial wilt and brown rot globally, fall into phylotype IIB sequevar 1 (IIB1), historically known as race 3, biolvar 2, i.e. *R. solanacearum*. Strains of both *R. pseudosolanacearum* and *R. solanacearum* can cause wilt in potato, but IIB1 strains are most persistent, can cause latent infections in tubers, are highly destructive and are cold tolerant.21

A study by Pule et al.19 showed that the US-1 clonal lineage predominates in potato production areas of southern Africa. However, the recent first report of the EU_33_A2 clonal lineage of *P. infestans* causing late blight in Nigeria is concerning, as this lineage is suspected to be more widely spread than previously thought. The introduction of a new pathogen population into an area is often followed by an increase in disease severity and subsequent negative socio-economic impacts. This might be the case in southern Africa should EU_33_A2 spread south on the continent.

Late blight control in developed nations is achieved through seed certification, integrated management, intensive fungicide spray programmes, early planting dates, elimination of inoculum and planting resistant cultivars. However, in developing nations, where systemic fungicides are not easily accessible or are unaffordable, growers often use large amounts of low-cost dithiocarbamate-type contact fungicides, in particular mancozeb, which presents significant health hazards to farmworkers and their families. It has been suggested that late blight in developed countries can be managed by phosphate applications, as a safer alternative to the hazardous dithiocarbamate derivatives currently used. Additional research is, however, needed to determine optimal timing, application rates, specific host reactions, environmental effects and interactions of phosphonates with other chemical compounds. The same level of control of the pathogen as that achieved by intensive spray programmes that incorporate both contact and systemic fungicides will not be attained by phosphate application alone.

Host resistance may be the most effective way for resource poor growers to manage late blight. However, the adoption of resistant cultivars in developing countries is often slow, because of the scarcity of functional seed certification systems and because *P. infestans* rapidly overcomes cultivar resistance, and there is therefore a lack of truly resistant varieties.

Bacterial wilt

Bacterial wilt (or brown rot) is another serious disease of potatoes that can result in substantial yield losses. It is caused by members of the *Ralstonia solanacearum* species complex (RSSC). The first symptoms of the disease are wilting of the young leaves of plants, which is most commonly observed at the hottest time of day. As the disease progresses, plants become stunted, display general wilting and chlorosis, and will eventually die. The most obvious symptoms are noted in tubers, as an initial brown discolouration of the vascular tissue, followed by rotting thereof (Figure 2a and 2b). Members of the RSSC globally were previously assigned to four phylotypes, with phylotype classification based on phylogenetic analysis of the 16S-23S ITS region. However, Safni et al. elevated these phylotypes to species level. The phylotypes generally correlate with the geographical origin of the strains: phylotype II originating from the Americas was assigned to *R. solanacearum*, strains in phylotype IV from Indonesia were assigned to *R. syzygii*, and strains in phylotype I and III originating from Asia and Africa were assigned to *R. pseudosolanacearum*. The most threatening potato pathogens, causing bacterial wilt and brown rot globally, fall into phylotype IIB sequevar 1 (IIB1), historically known as race 3, biolvar 2, i.e. *R. solanacearum*. Strains of both *R. pseudosolanacearum* and *R. solanacearum* can cause wilt in potato, but IIB1 strains are most persistent, can cause latent infections in tubers, are highly destructive and are cold tolerant.

RSSC is considered to be one of the most important phytopathogenic bacteria globally, because of the destruction it can cause, its wide geographical distribution and host range, and its ability to survive for extended periods in soil, water, on plant debris and in asymptomatic hosts. In southern Africa, bacterial wilt has been reported in Angola, Malawi, Mozambique, South Africa, Swaziland, Zambia and Zimbabwe. A report by Nortje indicated that, historically, the most important phylotypes in Africa are I and II, including the virulent IIB1 strains. There is, however, a dearth of recent documentation on the species causing bacterial wilt of potatoes in southern African countries, but it is assumed that both *R. pseudosolanacearum* and *R. solanacearum* are present.

Management strategies for bacterial wilt include planting pathogen-free seed tubers, avoiding cutting or dipping seed tubers, good...
management of root-knot nematodes, planting of resistant varieties, soil fumigation, crop rotation with non-hosts, treatment of irrigation water, and disinfection of implements, machines and equipment.\textsuperscript{29} Messiha et al.\textsuperscript{30} demonstrated the potential of biological soil disinfestation to reduce soil populations of \textit{R. solanacearum} through the incorporation of fresh organic matter into soil and then preventing the re-supply of oxygen into soils by covering with plastic. This practice results in shifts in the composition of bacterial communities, allowing biocontrol organisms to establish themselves in the soil.\textsuperscript{30} This practice may be a practical and affordable way for subsistence farmers in southern Africa to manage this devastating disease.

With the exception of South Africa, most southern African countries do not have formal or functional seed potato certification schemes. Growers thus rely on seed that is visually selected and saved from harvested tubers for the following seasons’ planting.\textsuperscript{29} This practice has resulted in the spread of \textit{R. solanacearum}, as growers usually select smaller tubers for seed, which are often latently contaminated with the pathogen.\textsuperscript{29} Numerous studies have shown that latently infected farm-saved seed is the primary source of inoculum and the pathway of dissemination of \textit{Ralstonia solanacearum} IIB1 in many countries in sub-Saharan and southern Africa, thus contributing substantially to the severity of bacterial wilt in these countries.\textsuperscript{26,29,31} The importance of seed inoculum is emphasised by the success of the South African Potato Certification Service in drastically reducing the incidence of bacterial wilt in both registered seed potato and table potato plantings since the inception of the scheme.\textsuperscript{28} This decrease in the disease in the commercial potato production sector of South Africa can be ascribed to strict implementation of a formal seed certification scheme, and good disease management practices.

Despite the many methods by which bacterial wilt can be managed, it still remains a yield-limiting disease in many countries in southern Africa\textsuperscript{26,33}, particularly for small-scale or subsistence growers. The wide host range and ability of the pathogen to survive for extended periods in soil and irrigation water renders many of the current potato practices useless in terms of reducing \textit{R. solanacearum} soil inoculum. The wide genetic diversity of \textit{R. solanacearum} hampers the success of cultivars bred for resistance against the pathogen, and makes detection and correct identification of the pathogen difficult, which in turn affects management decisions.\textsuperscript{26,33,34} An integrated pest management strategy – which combines numerous cultural, biological and chemical control measures – remains the most effective approach to reduce losses caused by \textit{R. solanacearum}. It is vital that potato growers in southern Africa implement as many of these practices as possible to avoid serious economic losses.

**Soft rot / blackleg disease complex**

The soft rot / blackleg disease complex caused by \textit{Pectobacterium} and \textit{Dickeya} species is a potential threat to potato production worldwide.\textsuperscript{35-38} The soft rotting Pectobacteriacea (SRP) cause systemic and vascular infections in potatoes, which result in the development of various symptoms on the stem and tubers.\textsuperscript{35-38} SRP, like \textit{R. solanacearum}, are considered to be among the top 10 most important bacterial phytopathogens globally, and cause significant losses in crop yield and quality.\textsuperscript{24} SRP are primarily tuber-borne, but environmental sources and contamination through wind currents, insects and irrigation water are established secondary routes.\textsuperscript{39-43}

Soft rot (Figure 3a) can occur in tubers at any stage (in the field, during harvest, post-harvest or in-store) and the disease will spread if a source of contamination is present and conditions are favourable for the development of the disease. The disease is most likely to occur in wet conditions with high temperatures.\textsuperscript{35} Blackleg (Figure 3b) develops when the bacteria in contaminated seed potatoes spread upwards in the stems.\textsuperscript{35,37} Aerial stem rot is a secondary soft rot of stems and leaves that develops after plants are wounded and subsequently infected by SRP.\textsuperscript{35,37}
The choice of crops in a rotation programme with potatoes is important. The symptoms of common scab of potatoes, caused by Spongospora subterranea f. sp. subterranea (Sss), the causal agent of root scab (Figure 4a) and powdery scab (Figure 4b) on potatoes, has been described as an emerging pathogen on potatoes. For many years, powdery scab was considered a minor disease on potatoes; however, it is rapidly becoming an increasing threat to potato production globally. The global increase in powdery scab intensity can be attributed to increased potato production, planting of susceptible cultivars, more frequent use of irrigation, and discontinuation of mercury-based soil and seed treatments. Only a few published records on the distribution of Sss in southern Africa are available. According to Manditsvara, powdery scab is a significant disease of potatoes in Zimbabwe. Likewise, research on powdery scab in South Africa has shown that this disease causes major economic losses to the potato industry in the country.

Control of Sss is difficult, but a reduction in disease incidence and severity can be achieved through integration of a number of management measures. These measures include informed selection of pathogen-free fields, cultivar choice, seed and soil treatment, optimal plant nutrition, crop rotation with non-hosts or trapping crops, planting of disease- and pathogen-free tubers, and post-harvest hygiene. As with bacterial wilt and late blight, the implementation of many of these control methods by smallholder or subsistence growers in southern Africa is, however, often problematic or impractical. A complicating factor in the management of powdery scab is the correct identification of symptoms. The symptoms of common scab of potatoes, caused by Streptomyces spp., and powdery scab, are difficult to distinguish; although favourable conditions for disease development and control measures for the two diseases are different. Accurate identification of symptoms is thus critically important for the management and containment of the disease. Many African countries, however, do not have active and accurate pest and pathogen diagnostic services for low-value staple crops, in particular, due to lack of expertise and the costs involved in establishing such services.

Most of the research on Sss in southern Africa has focused on management of powdery scab. Wright et al. demonstrated the importance of good hygiene and regular testing of growing media in the production of Sss-free mini-tubers in tunnels. Manditsvara and Simango and van der Waals established the potential of biofumigation and various soil treatments in suppressing root galling and powdery scab. These results may provide small-scale, subsistence and commercial growers with sustainable options for suppression of the pathogen in the soil.

The choice of crops in a rotation programme with potatoes is important. Growers should familiarise themselves with the host range of the pathogen and plant non-hosts or trapping crops in rotation with potatoes to prevent increase of the soil inoculum. No single management measure will control powdery scab; therefore, growers should use as many of the available options as possible to manage the disease.

Zebra chip disease

Zebra chip is an emerging potato disease that poses a serious threat to potato production worldwide, including in southern Africa. Symptoms in potato include leaf curling, yellowing or purpling of leaves or shoots, leaf chlorosis, shortened internodes with aerial tubers, and early necrosis. Potato tubers have necrotic flecking of the vascular tissue and streaks under the medullary rays. The name of the disease originates from potato slices that have brown blotches, stripes and streaks when fried. The disease is associated with the phloem-limited bacterium Candidatus Liberibacter solanacearum. The pathogen is transmitted in the field by the potato psyllid Bactericera cockerelli (Hemiptera, Triozidae), to potato and other solanaceous crops. Other psyllid species have been identified as vectors of ‘Ca. L. solanacearum’ to plants within the Apiaceae. Another route of infection is planting of infected plant material. The insect vector is native to North and Central America. The disease has been introduced into Europe and New Zealand, with the cause of spread not yet clear.

Pathways of introduction of the pathogen into southern Africa include importation of infected plant material or the infected insect vector. An integrated pest management approach is recommended, which includes the planting of certified disease-free material, conservation of natural enemies of the psyllid vector; application of insecticides and use of barriers for smaller areas to prevent the insect vector from reaching plants. The latter two strategies could be practically applied in southern Africa.

Discussion

Due to the vegetative propagation of potatoes by seed tubers, most of the important yield limiting pathogens are seed-borne and thus result in seed degeneration. Thomas-Sharma et al. define seed tuber degeneration as ‘an increase in pest and/or pathogen incidence or severity, associated with reduction in yield or quality of seed tubers over successive cycles of vegetative propagation’ and thus an indication
of decreasing seed health. Most farmers in developing nations, such as the majority of those in southern Africa, use farm-saved or poor-quality seed, which is often infected with various pathogens, or is physiologically inferior. This, along with the use of low-yielding varieties with little or no resistance to important diseases, poor disease management, and nutritionally depleted soils, results in low yields in these countries. The Agricultural Research Council of South Africa has a dedicated potato breeding programme, the aim of which is to release varieties that are adapted to local growing conditions in Africa. If sufficiently supported, the varieties developed through this breeding programme could contribute positively to sustainable potato production in other Southern African countries.

The introduction of specialised seed production systems, implementation of seed certification schemes, reduction in the cost of good-quality seeds, and alleviation of the bottleneck in the seed supply in developing African countries will improve potato production and sustainability. The production of seed tubers through a combination of tissue culture and aeroponics may also provide a viable alternative to conventional production of tubers for growers in developing countries. Aeroponics systems reduce the time and cost of production of seed, improve the growth and survival rate of plantlets, and are environmentally friendly. This approach will ensure the production of vast quantities of pathogen-free seed tubers for growers, and subsequently improve profitability of the farming operations.

As the demand for potatoes in southern Africa increases, growers often repeatedly crop potatoes in succession on the same fields, which leads to increases in pathogen inoculum in the soil and subsequent yield losses. Numerous studies have shown the importance of crop diversification and rotation in the suppression of pathogens, the optimisation of nutrient use efficiency, crop productivity and, when legumes are included in the cycle, minimisation of the dependence on external nitrogen applications.

Grower training plays a critical role in improving crop production. Demonstration plots and workshops run by regional extension officers should explain the importance of clean seed, crop rotation, hygiene, plant nutrition, and pest and pathogen management in potato production to growers. The success of such training efforts has been shown in Kenya and Swaziland inter alia.

One of the challenges encountered in gathering the information for this review was the lack of published data on disease occurrence and epidemiology, type of pathogen strains present, prevalence of pathogens or effect of diseases on potato production in southern Africa. Smith et al. made similar observations on the reporting of plant pests and pathogens in Africa, with the number of reports of new pest introductions in Africa having dropped over the last century compared to Europe. These discrepancies could be attributed to either the actual rate of introductions or the lack of plant protection expertise and capacity to report introductions in many African countries. Potato yield losses due to major pathogens in (central) Africa may be more than 50%, compared with 24% in northern Europe, indicating clear differences in crop protection intensity between these two regions.

These observations imply that Africa is ill-prepared for pest or pathogen introductions, which could threaten production of staple crops, such as potatoes. Improved border control, plant quarantine or monitoring of the movement of pathogens is imperative to prevent incursions of pathogens into new areas. Border porosity and lack of enforcement of plant quarantine of monitoring services in Africa results in unhindered movement of pests and pathogens across both regional and national borders on the continent, and should receive urgent attention to ensure food security in southern Africa.
